Topic 3: Moving the Goalposts Approach

by Sai Zhang

Key points:

•

Disclaimer: These notes are written by Sai Zhang (email me or check my Github page). The main reference for this topic is Armstrong, Kolesár, and Kwon (2020), I thank Prof. Armstrong for his valuable advice.

3.1 Finite Sample Bias-Variance Tradeoffs

3.1.1 **Setup**

Consider the fixed design regression model

$$y_i = w_i \beta(z_i) + h(z_i) + \epsilon_i \tag{3.1}$$

where

- w_i, z_i are treated as **fixed**
- ϵ_i is **independent**, with $\mathbb{E}[\epsilon_i] = 0$, $\mathbb{E}[\epsilon_i^2] = \sigma_i^2$
- observation: $\left\{ \left(y_i, w_i, z_i' \right)' \right\}_{i=1}^n$

one example is the case where w_i is **binary**, then

$$\beta(z) = f(1, z) - f(0, z)$$

which is just the ATE conditional on z under the unconfoundedness assumption. This includes the RD design, where z_i is the running variable and w_i is the treatment assignment.

Now, consider for the weighted average treatment effect

$$L_{\mu}\left[\beta(\cdot)\right] = \int \beta(z) \mathrm{d}\mu(z)$$

where $\int \mu(z) = 1$ is a **signed** measure (weight, allowing **negative** weights), construct a linear estimator

$$\hat{L}_a = \sum_{i=1}^n a_i y_i$$

where the estimation weights a_i can depend on $\{z_i, w_i, \sigma_i^2\}_{i=1}^n$, but **not** on y_i . Together, the bias of \hat{L}_a for $L_{\mu}\left[\beta(\cdot)\right]$, given the regression function $\beta(\cdot)$, $h(\cdot)$, is

$$\mathbb{E}_{\beta(\cdot),h(\cdot)}\left[\hat{L}_a\right] - L_{\mu}\left[\beta(\cdot)\right] = \sum_{i=1}^n a_i \left[w_i\beta(z_i) + h(z_i)\right] - \int \beta(z) \mathrm{d}\mu(z)$$

and its variance, given the regression function $\beta(\cdot)$, $h(\cdot)$, is just

$$\operatorname{Var}_{\beta(\cdot),h(\cdot)}\left[\hat{L}_{a}\right] = \sum_{i=1}^{n} a_{i}^{2} \sigma_{i}^{2}$$

To bound the bias, assume $h(\cdot)$ is known to belong in a class of functions \mathcal{H} , then two approaches can be adopted, for the regularity of $\beta(\cdot)$ and the choice of $\mu(\cdot)$:

1 arbitrary $\beta(\cdot)$, optimizing weights μ by *moving the goalposts*, s.t. $L_{\mu}\left[\beta(\cdot)\right]$ is easy to estimate (Crump et al., 2006; Imbens and Wager, 2019) which gives the worst-case bias

$$\inf_{\mu} \sup_{\beta(\cdot),h(\cdot)} \left| \sum_{i=1}^{n} a_i \left[w_i \beta(z_i) + h(z_i) \right] - \int \beta(z) d\mu(z) \right| \qquad \text{s.t. } h(\cdot) \in \mathcal{H}, \int d\mu(z) = 1 \qquad (3.2)$$

2 assume constant treatment effects, i.e., $\beta(z) = \beta$, $\forall z$, which means that $L_{\mu}\left[\beta(\cdot)\right] = \beta$ regardless of μ (Armstrong et al., 2020), and the worst-case bias is

$$\sup_{\beta,h(\cdot)} \left| \sum_{i=1}^{n} a_i \left[w_i \beta + h(z_i) \right] - \beta \right| \qquad \text{s.t. } h(\cdot) \in \mathcal{H}$$
 (3.3)

And, the two approaches can be linked as such:

• If $\sum_{i=1}^{n} a_i w_i = 1$, 3.2 and 3.3 are both equal to

$$\sup_{h(\cdot)} \left| \sum_{i=1}^{n} a_i h(z_i) \right| \text{ s.t. } h(\cdot) \in \mathcal{H}$$
 (3.4)

- 3.2 automatically equals 3.4
- 3.3 is optimized (w.r.t. μ) by setting μ to place weight $a_i w_i$ on observation i, i.e., $\mu(\mathcal{Z}) = \sum_{i:z_i \in \mathcal{Z}} a_i w_i$, which implies $\sum_{i=1}^n a_i w_i \beta(z_i) \int \beta(z) d\mu(z) = 0$, hence the equality.
- Otherwise, 3.2 and 3.3 are both infinite:
 - 3.3 can be made arbitrarily large by choosing large enough β
 - 3.2 can be made arbitrarily large by making $\beta(\cdot)$ constant (as in 3.3) and large enough

3.1.2 Moving-the-goalpost Approach

3.1.3 Constant-treatment-effect Approach

Armstrong et al. (2020) adopt this approach, focusing on the case where $h(\cdot)$ is a high dimensional linear function, and the penalty function is an l_p norm of the coefficients.

Basic setting: Homoskedastic Gaussian errors

First, consider

$$Y = w\beta + Z\gamma + \epsilon \tag{3.5}$$

where

- $\beta \in \mathbb{R}$ is the constant treatment effect to be estimated
- $\gamma \in \Gamma$ is the control coefficients, subject to the restriction (i.e., the function class \mathcal{H})

$$\Gamma = \Gamma(C) = \left\{ \gamma \in \mathcal{G} : \text{Pen}(\gamma) \le C \right\}$$
(3.6)

where $Pen(\cdot)$ is a seminorm¹ on some linear subspace \mathcal{G} of \mathbb{R}^k .

- $w = (w_1, \dots, w_n)' \in \mathbb{R}^n$ and $Z = (z_1', \dots, z_n')' \in \mathbb{R}^{n \times k}$ are defined as before
- $\epsilon \sim \mathcal{N}\left(0, \sigma^2 I_n\right)$ is assumed **normal and homoskedastic**, with σ^2 known

For estimation, the goal is to construct estimators and CIs for β :

• estimator $\hat{\beta}$: consider the worst-case performance over the parameter space $\mathbb{R} \times \Gamma$ under the **MSE** criterion

$$R_{MSE}\left(\hat{\beta};\Gamma\right) = \sup_{\beta \in \mathbb{R}, \gamma \in \Gamma} \mathbb{E}_{\beta,\gamma}\left[\left(\hat{\beta} - \beta\right)^{2}\right]$$

•

¹Seminorm satisfies **triangle inequality** Pen $(\gamma + \tilde{\gamma}) \le \text{Pen}(\gamma)$ and **homogeneity** Pen $(c\gamma) = |c| \text{Pen}(\gamma)$, $\forall c$, but **NOT** necessarily positive definite (Pen(γ) = 0 does not imply γ = 0). Essentially, any convex set Γ that is symmetric satisfies this definition.
